# Mapping the Conjugate Gradient Algorithm onto High Performance Heterogeneous Computers

## **ABSTRACT**

### **ABSTRACT**

Mapping scientific kernels onto high performance heterogeneous computers (HPHC) must comply with certain rules of thumb or heuristics. Previous research by Jackson State University's (JSU) HPHC research group has provided anecdotal evidence illustrating some of these rules/heuristics. The research highlighted by this thesis corroborates the credibility of these rules. In particular, four versions (two pairs) of a floating-point sparse matrix conjugate gradient (CG) iterative solver are presented. JSU's state-of-the-art HPHC utilizes general purpose processors (GPP) and heterogeneous computational hardware, in particular, a field programmable gate array (FPGA), to develop the CG kernels. The first version of the pair executes strictly on the GPP and the second uses both the GPP and FPGA to map the entire CG algorithm onto hardware. For the second pair, a refactored version of CG is used, which is statically analyzed to determine where the most computationally expensive operation occurs. This operation is the sparse matrix vector multiply (MVM) kernel. Based on this analysis, the software version of CG is refactored to call MVM as a subroutine. An FPGA version of the MVM algorithm is also developed and a static analysis of that algorithm suggests a speedup of the MVM kernel. All four version of CG are executed using a specially designed set of sparse matrices and the results demonstrate that adherence to the rules of thumb and heuristics when mapping scientific kernels onto a HPHC can lead to significant speedups.

## ACKNOWLEDGMENTS

First and foremost I would like to thank Jesus Christ for leading me out of the darkness and blessing me with knowledge and wisdom. To my mother and grandparents, words cannot begin to comprehend how much your unwavering support in my endeavors motivated me to grow stronger and go harder throughout the trials and tribulations that crossed my path. To my sisters, Shelnaka and Rashia, thank you for always believing and expecting the best of me. I would like to thank the faculty, staff, and administration at Jackson State University for creating a superior learning environment.

This work was supported in part by the U.S. Army Research Office under contract numbers W911NF-13-1-0133, Exploring High Performance Heterogeneous Computing via Hardware/Software Co-Design, and in part by the U.S. Army Engineer Research and Development Center. I would definitely like to thank my two advisors, Dr. Khalid Abed and Dr. Gerald Morris, for selecting me out of dozens of students to participate in this research program. I have learned from you tremendously both in the technical and professional aspect. I am proud to call you my mentors and without your support and guidance, I would not be the person I am today. To Mr. Anas Alfarra, Mr. Christopher Robinson, Mr. Michael Knight, and countless others that have been with me on this journey since day one, thank you for your companionship, more importantly, your friendship. Having someone to share your joy, pain, ups and downs, builds bonds and

lasting memories. Thank you for letting me lean on you when times got hard. I will forever be grateful for you.

## ABSTRACT

Mapping scientific kernels onto high performance heterogeneous computers (HPHC) must comply with certain rules of thumb or heuristics. Previous research by Jackson State University's (JSU) HPHC research group has provided anecdotal evidence illustrating some of these rules/heuristics. The research highlighted by this thesis corroborates the credibility of these rules. In particular, four versions (two pairs) of a floating-point sparse matrix conjugate gradient (CG) iterative solver are presented. JSU's state-of-the-art HPHC utilizes general purpose processors (GPP) and heterogeneous computational hardware, in particular, a field programmable gate array (FPGA), to develop the CG kernels. The first version of the pair executes strictly on the GPP and the second uses both the GPP and FPGA to map the entire CG algorithm onto hardware. For the second pair, a refactored version of CG is used, which is statically analyzed to determine where the most computationally expensive operation occurs. This operation is the sparse matrix vector multiply (MVM) kernel. Based on this analysis, the software version of CG is refactored to call MVM as a subroutine. An FPGA version of the MVM algorithm is also developed and a static analysis of that algorithm suggests a speedup of the MVM kernel. All four version of CG are executed using a specially designed set of sparse matrices and the results demonstrate that adherence to the rules of thumb and heuristics when mapping scientific kernels onto a HPHC can lead to significant speedups.

## CHAPTER 1

### INTRODUCTION

#### 1.1 History and Thesis Organization

High Performance Heterogeneous Computers (HPHC) have consistently delivered superior performance for their targeted application as opposed to their microprocessor based counterpart. Despite this significant speed-up, only a sparse number of applications were considerable to justify the design, development, and support costs of an HPHC (SRC Computers, LLC 2010). This is why mainstream supercomputing companies such as Cray and SGI have had HPHC offerings in the past but with fleeting commercial success, however, Seymour R. Cray's startup company, SRC Computers (SRC Computers, LLC 2010), has had some commercial success in the HPHC space (Jane's Information Group 2011). This success is partially attributable to their Carte compiler, which integrates their proprietary MAP processors and user-specific applications written in Fortran and/or C, into a single application executable code (SRC Computers Inc. 2014).

Previously, most complex systems in communications, military, and medical applications were simulated or modeled using floating-point data processing in C or MATLAB, which is a widely used program for solving algebraic and differential equations. However, the lack of support with field programmable gate array (FPGA) tool suites made floating-point arithmetic an unappealing option for the FPGA designer,

thus, final implementations were nearly always performed using fixed-point or integer arithmetic (Parker 2009). With the recent advancements in FPGA technologies, companies such as Altera now offer single and double precision floating intellectual property (IP) cores fashioned specifically for high performance applications. Tools such as Altera’s MegaWizard Plug-In Manager (Altera Corp. 2011) takes the hassle out of custom IP core manufacturing by automatically generating optimized floating-point IP cores within the FPGA itself. Such IPs have been successfully mapped onto HPHCs (Peay, Morris, and Abed 2011) and floating-point kernels targeting specific problem domains such as molecular dynamics have been demonstrated (Scrofano, Gokhale, Trouw, and Prasanna 2006; Herbordt, Khan, and Dean 2009), as have general-purpose kernels such as linear algebra routines (Zhuo and Prasanna 2005b; Zhuo and Prasanna 2005a; Wu, Dou, Lei, Zhou, Wang, and Jiang 2009). There has even been some success at mapping iterative solvers onto FPGAs (Roldao and Constatinides 2010; Morris and Prasanna 2006; Morris and Prasanna 2007).

For numerical and computational applications, these FPGA-based processors must satisfy a variety of heuristics and rules of thumb to achieve a speedup compared with their software counterparts. This thesis illuminates the challenging computational mapping process while simultaneously showing that such mappings can result in significant speedups. Its major focus is to demonstrate the veracity of the concept “the three P’s” which expresses the crucial relationship among performance, pipelining, and parallelism, which is perhaps the most important mapping consideration (Morris and Abed 2013). In

addition, portions of this thesis is referenced from the paper which will be submitted to the International Conference on Engineering of Heterogeneous Systems and Algorithms (ERSA) (Hawkins, Alfarra, Morris, and Abed ). This research paper is organized into five chapters. Chapter 1 begins with the introduction which identifies the problem and presents the significance of this research. Chapter 2 discusses previous work and literature that proves pivotal in the area of attaining a speedup on a HPHC. Chapter 3 discusses the tools, technology, and methodology used in conducting this research. Chapter 4 presents the results derived from this research and analyzes the platforms performance levels. Lastly, Chapter 5 concludes with future work related to achieving speedup with HPHCs.

## 1.2 Research Objective

The results and conclusions obtained from this research may be applied to various HPHC areas. By way of a sparse matrix conjugate gradient (CG) iterative solver, this paper illustrates some of the issues associated with mapping scientific kernels onto HPHCs. The CG method was chosen based on heuristics developed from earlier research(Rice, Abed, and Morris 2009; Morris and Abed 2013; Morris, McGruder, and Abed 2010). Furthermore, CG is a method that is frequently used in the real world and complex enough to deal with issues of mapping scientific kernels onto FPGAs.

In this research, four versions (two pairs) of CG were mapped on to a HPHC. The first version of the pair executes strictly on the general purpose processor (GPP) in JSUs state-of-the-art HPHC, and the second utilizes both the GPP and the heterogeneous

computational hardware, in particular, a field programmable gate array (FPGA). Not too surprisingly, the first hardware version does not perform very well because it does not consider the rules and heuristics that will be discussed in this thesis.

The second pair, which is a profiled version of CG, is statically analyzed to determine where the most computationally expensive operation occurs. This operation is the sparse matrix vector multiply (MVM) kernel. Based on this analysis, the software version of CG is refactored to call MVM as a subroutine. This software version is then profiled to determine the percentage of runtime spent in MVM. This factor is called the fraction that can be enhanced ( $f_e$ ) in Amdahl's Law. A hardware (FPGA) version of the MVM algorithm is also developed and a static analysis of that algorithm suggests a speedup of the MVM kernel. This factor is called the speedup of the enhanced component ( $s_e$ ) in Amdahl's Law.

The combination of these two factors ( $f_e$  and  $s_e$ ) are used in Amdahl's Law to estimate the anticipated overall speed ( $s_o$ ) up of the HPHC version of CG. The second HPHC version performs significantly better than the first because the rules and heuristics (to be described later) are followed, i.e., MVM was a great candidate for kernel mapping onto a HPHC to achieve an overall speedup of CG.

## CHAPTER 2

### LITERATURE REVIEW

This chapter discusses the necessary background information that serves as a platform for this research. This chapter is partitioned into 7 sections. The first gives rise to a particular type of HPHC as it examines the history and early mappings of FPGAs. Section two discusses heterogeneous computers (RC) and their physical architecture. Section three details the history and significance of the conjugate gradient algorithm. The fourth section discusses matrix storage formats and their crucial importance in scientific research. Section five examines the types of matrices and their importance as well. Section six discusses in detail the HPHC target platform; the SRC-7. The seventh and final section of this chapter details Amhdal's Law which is an approach for calculating the overall speed up of a system when only part of the system has been enhanced.

#### 2.1 FPGAs

##### 2.1.1 History

Field programmable gate arrays are a programmable digital logic device (PLD). It was invented in 1984 by Xilinx co-founder Ross Freeman (Xilinx, Inc. 2006). At the time it was groundbreaking due to its ability to be dynamic in application. However, it operated at much slower speeds than Application-Specific Integrated Circuits (ASICs). It also used

more transistors than its fixed competitor. With the reduction in transistor cost, over time, FPGAs have become widespread in use.

### 2.1.2 Architecture

The physical architecture of an FPGA, as shown in Figure 2.1, consists of various components that are able to communicate via switches. These switches are directional and allow multi-point interconnection between components. Fixed logic blocks consist of, but are not limited to, the central processing unit (CPU), random access memory (RAM), and clock. Input/output (I/O) blocks allow for data to be made available to the FPGA as well as provide output from the application. Configurable logic blocks (CLBs) are structures that are used to emulate digital logic functions.

As shown in Figure 2.2, CLBs consist of multiple slices that are internally connected aside from the FPGA component routing mechanism. A deeper look into the slices reveals the components that allow for the FPGAs configurable design. Slices are comprised of multiple lookup tables (LUTs), flip-flops, multiplexers, and control. The CLB mimics a digital logic function set in place by the developer due largely in part to the lookup tables (LUTs) that lie within the slices. LUTs directly resemble digital logic using memory, as depicted in Figure 2.3.

At runtime, the FPGA is programmed with a configuration bitstream (the bitstream is viewed as data, but it is the driving force of the conversion of the FPGA). It defines the contents of LUTs, interconnections between components, and input or output

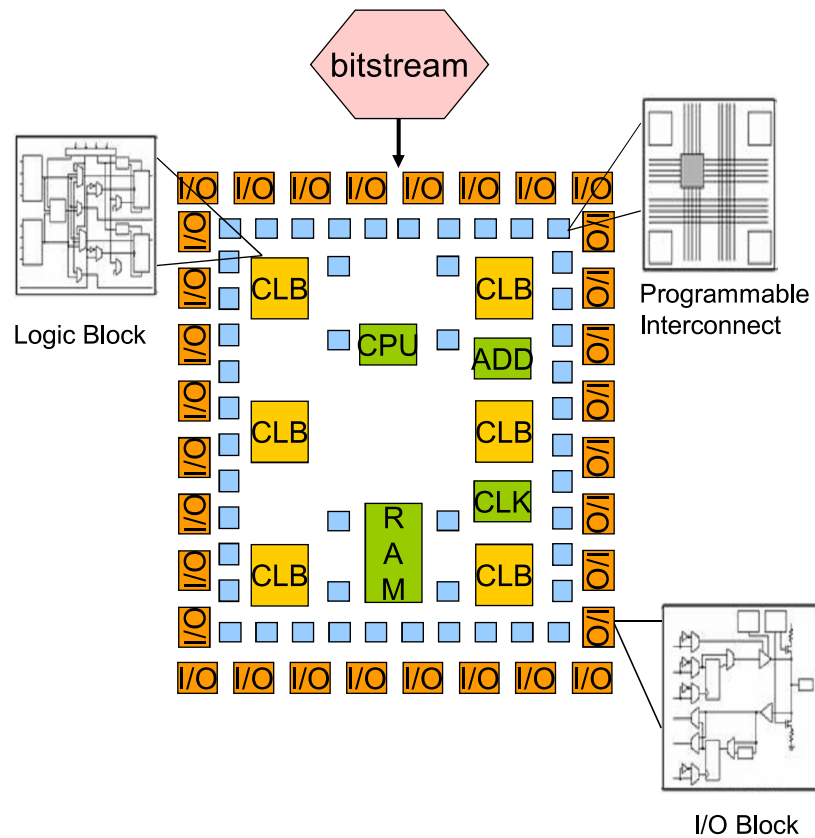

Figure 2.1 FPGA Architecture

(I/O). Hence, a different application implemented on an FPGA lies solely within the corresponding bitstream. The FPGA is thereby dynamic in functionality though it is limited in speed capability in comparison to its ASIC competitor. If a new application is to be developed, there is no need for “hard wiring” as in the historical process. Nonetheless, it is not to be assumed that generating the corresponding bitstream is a trivial task - for this now takes many steps and design considerations by the developer.

Figure 2.2 CLB architecture

Figure 2.3 Lookup Table

### 2.1.3 FPGA Benefits and Applications

FPGAs have gained popularity as a platform for scientific computation applications. If inadequately designed, the platform may significantly decrease performance (Zhuo, Morris, and Prasanna 2007). Developers have also used the FPGAs to create significant increases over comparable platforms in application-specific integrated circuits (ASICs). For example, a 1800x increase in training speed has been obtained with Rankboost web search engines over its prior implementation using only a GPP (Xu, Cai, Gao, Zhang, and Hsu 2009). A 5.5 fold speedup in pair-wise computations was actualized by Nallamuthu et.al using the heterogeneous computing environment. FPGAs provide the potential for

high performance with less power consumption. Under the aforementioned development, a nine fold increase in the ratio of power to performance also gave an added benefit to using a heterogeneous environment involving an FPGA architecture (Nallamuthu, Smith, Hampton, Agarwal, and Alam 2010).

## 2.2 Heterogeneous Computers

Heterogeneous computing is a technology that encapsulates fixed and variable structures. It allows the developer to modify the architecture of a processing element. Unlike fixed hardware, the variable hardware is able to be adapted to a new platform in real time. The RC concept was invented in 1960 by Gerald Estrin. At the time, research and development efforts proved impractical. Developers would have to manually place modules and wire them according to the anticipated configuration. This lengthy approach was highly susceptible to human errors, and circuits would be limited in size. Presently, the manual process has been replaced with digital control switches that allow the variable structure to be configured through programming. Contemporary high performance heterogeneous computing (HPHC) clusters vary with its models and architectures. It may consist of multiple nodes of RCs to create parallelism in computation and task execution.

### 2.2.1 Application mapping

An application may be realized solely in software running on a GPP. This process usually involves code written in a high-level language that is compiled and linked with

system libraries to produce a binary executable. On a GPP with a single processor, each task is executed sequentially. Here, the developer's primary avenue of attaining a speedup is through optimizing the code. With an application placed on a heterogeneous computer, the fixed component generally calls for a GPP, and the variable component may be an FPGA. The application is developed and placed on an RC if deemed more profitable in terms of speedup. This concept is illustrated in Figure 2.4. It is important to analyze the potential of a computationally intensive kernel that is to be successfully placed on an FPGA. The developer strategically evaluates design considerations of the application. This is determined through various metrics that analyze its application size, algorithm, and memory-access patterns (Rice, Abed, and Morris 2009).

In order to profile the potential of an computational kernel that is to be placed onto the FPGA, the developer takes various design elements into consideration. In terms of runtime, the developer must analyze the kernel and determine its overall effect on the entire application. Its particular algorithm is evaluated as the developer must examine the kernel size in relation to space available on the FPGA. Concerning the entire RC layout, one must also consider memory access patterns. The bandwidth available for communication between the fixed and variable elements should be capable to transfer data without creating a significant increase in the overall runtime. If so, some of this time lost in transfer among elements may be alleviated through data reuse once it is placed onto the variable computing environment. This research considers a dot product for its computational kernel.

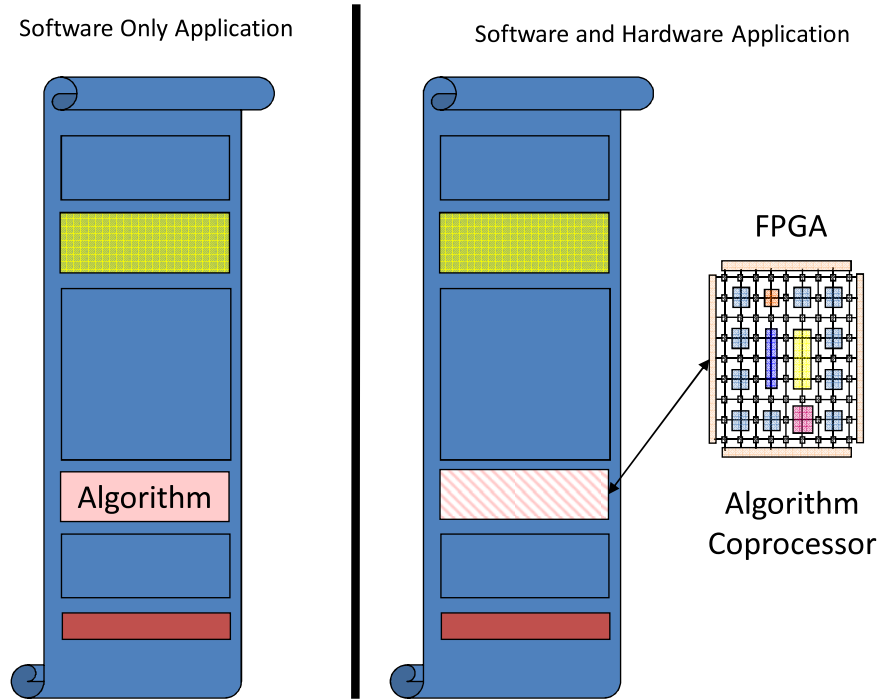

Figure 2.4 Application Mapping

### 2.3 Conjugate Gradient

The Conjugate Gradient (CG) method, which was discovered in 1952 by Hestens and Stiefel, is an algorithm typically used to solve large and sparse systems of linear equations,  $Ax = b$ . The method was abandoned in the 1960s due to a lack of finite precision computational engines which caused the algorithm to diverge, thus, rendering it useless. In 1971, however, mathematician J.K. Reid indicated that CG, if observed

as an iterative method rather than an  $n$  step process, will ultimately converge with veritable accuracy (Paige and Saunders 1975). Today, the Conjugate Gradient method is acknowledged as one of the top 10 algorithms of the twentieth century (Van der Vorst 2000). It is the de facto standard algorithm for solving equations that involve symmetric positive definite (SPD) matrices (Morris 2013).

### 2.3.1 CG algorithm

This section discuss conjugate gradient as an iterative method to solve systems of linear equations

$$A\mathbf{x} = \mathbf{b} \quad \equiv \quad \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} = \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{bmatrix} \quad (2.1)$$

where  $A \in \mathbb{R}^{n \times n}$  is a symmetric ( $A = A^T$ ) positive definite ( $\forall \mathbf{x} \neq 0, \mathbf{x}^T A \mathbf{x} > 0$ ) matrix,  $\mathbf{x} \in \mathbb{R}^n$  is the unknown vector (our desired solution), and  $\mathbf{b} \in \mathbb{R}^n$  is the constant vector.

It can also be shown that the solution  $A\mathbf{x} = \mathbf{b}$  is the same as the  $\mathbf{x}$  vector that minimizes the quadratic function,

$$f(\mathbf{x}) = \frac{1}{2} [x_1 \ x_2 \ \cdots \ x_n] \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} - [x_1 \ x_2 \ \cdots \ x_n] \begin{bmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{bmatrix}.$$

i.e.,  $\nabla f(\mathbf{x}) = 0 = A\mathbf{x} = \mathbf{b}$ , which is also a linear combination of  $A$ -orthogonal(conjugate) vectors  $\{\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_n\}$  that forms a basis for  $\mathbb{R}^n$ .

$A\mathbf{x} = \mathbf{b}$  can also be expressed in Equation 2.2 as

$$\mathbf{x} = \sum_{i=1}^n \alpha_i \mathbf{p}_i. \quad (2.2)$$

Finding the  $A$ -orthogonal vectors is a non-trivial task; therefore, an iterative approach is used. In particular, it can be shown that each of these vectors correspond to a search direction, therefore, the iterative approach is in effect a gradient descent method that minimizes the quadratic function previously mentioned. After each step in the given direction there is a residual,  $\mathbf{r}_k$ , which in a sense indicates how far off the solution is (Morris 2013). It can be shown that these search directions are in a direction negative of the gradient at the starting point, hence, the term “*conjugate gradient*”. Think of “zig-zagging” to the bottom of a bowl. Performing this type of gradient descent with infinite precision, the iteratively generated set of  $A$ -orthogonal vectors would correspond to a basis for  $\mathbb{R}^n$  as depicted in Figure 2.5.

Via some algebraic manipulations this approach can be refined to a recursive technique, however, one of the issues with this technique is that the residual contains components in the search direction that have already been taken. Remember, the next search direction must be  $A$ -orthogonal. It is necessary to remove these components from the residual in order to calculate a new search direction via the projection operator  $\beta$  which can be observed as  $\beta_k = \frac{\mathbf{r}_k^T \mathbf{r}_k}{\mathbf{r}_{k-1}^T \mathbf{r}_{k-1}}$ . Before discussing the final algorithm, one detail

```

1: algorithm PRIMITIVECG( $A, \mathbf{x}, \mathbf{b}$ )

2:   Using current point, calculate residual,  $\mathbf{r}_k \leftarrow \mathbf{b} - A\mathbf{x}_k$ 

3:   Calculate next conjugate vector,  $\mathbf{p}_{k+1} \leftarrow \mathbf{r}_k - \sum_{i \leq k} \beta_{ik} \mathbf{p}_i$ 

4:   Descend to the next point  $\mathbf{x}_{k+1} \leftarrow \mathbf{x}_k + \alpha_{k+1} \mathbf{p}_{k+1}$ 

5:   If not the minimum point, goto 2

6: end algorithm

```

Figure 2.5 Primitive CG algorithm

that needs to be mentioned is the classical residual norm. This is a standard approach used in iterative methods such as CG, Jacobi, Newton-Raphson, etc.

After a further improvements, an optimized version of CG is realized in Figure 2.6. With this approach, an arbitrary starting point  $\mathbf{x}_0$  was selected which then descended. The first A-orthogonal vector,  $\mathbf{p}_1$ , is a search direction opposite to the gradient as depicted in line 2, therefore, the initial search direction is also the same as the initial residual as illustrated on line 3. The next line is a criteria for forcing the algorithm to enter the loop. Line 5, as mentioned previously, is part of the equation for calculating the residual. Rather than continually computing this value, it is simply calculated one time. For line 6, the body of the loop requires the dot product of the current residual,  $\mathbf{r}_k$ , and the previous residual,  $\mathbf{r}_{k-1}$ . Instead of calculating two dot products within the loop, the dot product from the previous iteration was reused, i.e.,  $\mathbf{r}_0^T \mathbf{r}_0$  is a dot product. Line 7 creates the

```

1: algorithm OPTIMIZEDCG( $A, \mathbf{x}, \mathbf{b}$ )
2:    $\mathbf{p}_1 \leftarrow \mathbf{b} - A\mathbf{x}_0$ 
3:    $\mathbf{r}_0 \leftarrow \mathbf{p}_1$ 
4:    $\Delta \leftarrow \epsilon + 1$ 
5:    $\text{over}b_{\text{norm}} \leftarrow 1/\|\mathbf{b}\|$ 
6:    $rTr_{\text{old}} \leftarrow \mathbf{r}_0^T \mathbf{r}_0$ 
7:    $k \leftarrow 1$ 
8:   while ( $\Delta > \epsilon$ ) .AND. ( $k < k_{\text{max}}$ ) do
9:      $\mathbf{v}_{ap} \leftarrow A\mathbf{p}_k$ 
10:     $\alpha_k \leftarrow rTr_{\text{old}}/\mathbf{p}_k^T \mathbf{v}_{ap}$ 
11:     $\mathbf{x}_k \leftarrow \mathbf{x}_{k-1} + \alpha_k \mathbf{p}_k$ 
12:     $\mathbf{r}_k \leftarrow \mathbf{r}_{k-1} - \alpha_k \mathbf{v}_{ap}$ 
13:     $rTr_{\text{new}} \leftarrow \mathbf{r}_k^T \mathbf{r}_k$ 
14:     $\beta_k \leftarrow rTr_{\text{new}}/rTr_{\text{old}}$ 
15:     $rTr_{\text{old}} \leftarrow rTr_{\text{new}}$ 
16:     $\mathbf{p}_{k+1} \leftarrow \mathbf{r}_k + \beta_k \mathbf{p}_k$ 
17:     $\Delta \leftarrow \|\mathbf{r}_k\| \cdot \text{over}b_{\text{norm}}$ 
18:     $k++$ 
19:   end while
20:   return ( $\mathbf{x}_{k-1}$ )
21: end algorithm

```

Figure 2.6 Optimized CG algorithm

iteration index,  $k$ , which is also part of the criteria for the while loop to stop infinite looping.

It can be shown that the matrix vector product is needed twice within CG, however, it is computed once on line 9 because it is an expensive  $\mathcal{O}(n^2)$  algorithm. The next line computes the step size,  $\alpha_k$ , along the direction of the CG. For line 11, the new approximation for  $\mathbf{x}$  is calculated by descending in the conjugate search direction of the step size, i.e.,  $\mathbf{x}_{k-1} + \alpha_k \mathbf{p}_k$ . Line 12, recursively computes the new residual. Then the dot product of the new residual,  $rTr_{\text{new}}$  is calculated, which will be used in subsequent computations. Line 14 computes the projection operator  $\beta$  which removes from the

residual all previous search directions. Since the dot product of the previous residual is no longer needed and to prevent calculating the dot product at the next iteration, line 15 retains the current residual for the next iteration. The new search direction can finally be calculated, by using the projection operator to remove the residual from all components along the previous conjugate search directions, i.e.,  $\mathbf{r}_k + \beta_k \mathbf{p}_k$ . Line 17 computes the residual norm to check the algorithm for convergence. Line 18 simply increments the iteration index. If the algorithm has converged, the solution,  $\mathbf{x}_{k-1}$ , is returned.

This optimized version will become the blueprint for the four versions of CG as discussed in Chapter 3.

## 2.4 Sparse Matrix Storage Formats

According to J. Dongarra (Dongarra 2000), the efficiency of most iterative methods, such as CG, can be attributed to the performance of the matrix-vector multiply which correlates directly to the storage scheme used for the matrix. The reasoning behind these formats begins with the concept “sparse matrix”. A matrix is considered sparse if there are more zero than non-zero elements, in which case, it is more efficient to store only the non-zero elements because memory consumption can be reduced and performance can be increased by using a specialized sparse storage representation (B. Jacobs 2013). Sparse storage schemes allocate contiguous storage in memory for the nonzero elements, which in turn requires a scheme for knowing where the elements fit into the full matrix (Dongarra 2000), i.e., storing all non-zero elements of the matrix into a linear array and

providing auxiliary arrays to describe the locations of the non-zero elements in the original matrix (D. Dodson and Lewis 1991). Coordinate format (COO) and Compressed Sparse Row (CSR) are the primary sparse matrix representations used throughout this research and shall be discussed in depth.

#### 2.4.1 Coordinate Format

Also known as the ‘ijv’ or ‘triplet’ format, COO form is the simplest method to construct a matrix. It allows for very fast conversion to and from CSR format for arithmetic and matrix vector operations (Scipy 2009). COO format uses the vectors **row**, **col**, and **val** to store the row indices, the column indices, and values of the matrix, respectfully. For example, a 5 x 5 matrix is depicted in Fig. 2.7.

7	0	0	2	0
0	3	0	0	5
2	0	6	1	1
0	4	7	0	0
9	3	0	0	4

Figure 2.7 Simple 5 x 5 matrix

This simple matrix can be easily converted to COO format as shown in Fig. 2.8. Given an index,  $i$ , that walks each element of the three vectors *Row*, *Column*, *Value*, one can easily reconstruct the original matrix.

<b>row</b>	1	1	2	2	3	3	3	3	4	4	5	5	5
<b>col</b>	1	4	1	5	1	3	4	5	2	3	1	2	5
<b>val</b>	7	2	3	5	2	6	1	1	4	7	9	3	4

Figure 2.8 Example of COO format

#### 2.4.2 Compressed Sparse Row

If a matrix has a small number of nonzero values,  $n_z \ll n^2$ , where  $n$  is the matrix order and  $n_z$  is the number of nonzeros, CSR format (Saad 2009) can reduce storage and computational requirements. A real matrix with  $n = 1,024$  and  $n_z = 4,096$ , which requires 4MB in dense format, can be stored in CSR format in about 36KB. Furthermore, needless computations with zero values can be avoided. For a real matrix of order  $n$  with  $n_z$  nonzeros, CSR uses vectors **val**, **col**, and **ptr** to store only the nonzero values and to identify the associated row and column indices. Vector **val** is a real vector of length  $n_z$  containing the nonzero values obtained from a row-wise traversal of the matrix. The **col** integer vector is also of length  $n_z$  and contains the column index of each nonzero value, i.e.,  $(val_h = a_{ij}) \Rightarrow (col_h = j)$ . The **ptr** integer vector is of length  $n + 1$  and contains the index in **val** where each matrix row starts. For example, the first nonzero element of matrix row  $m$  is found at index  $ptr_m$  of **val**. By convention,  $ptr_{n+1} \equiv n_z + 1$ . Notice that  $(a_{ij}) \Rightarrow (ptr_i \leq j < ptr_{i+1})$  for all  $i$ . An example, depicting the CSR representation of an order  $n = 4$  sparse matrix, is shown in Fig. 2.9. Consider  $ptr_3 = 5$ ; this indicates that row

$\begin{bmatrix} 8 & 0 & 2 & 3 \\ 0 & 5 & 0 & 0 \\ 0 & 0 & 6 & 1 \\ 0 & 4 & 0 & 7 \end{bmatrix}$	$n=4$		1 2 3 4 5 6 7 8
	$\iff$	<b>val</b>	8 2 3 5 6 1 4 7
	$n_z=8$	<b>col</b>	1 3 4 2 3 4 2 4
		<b>ptr</b>	1 4 5 7 9

Figure 2.9 Example of CSR format

3 of the matrix begins at index 5 of **val** and **col**. Notice that  $val_5 = 6$  and that  $col_5 = 3$ .

Thus,  $a_{3,3} = 6$  as in the dense representation of the matrix.

#### 2.4.3 Aligned CSR Format

For the CG processor described in this paper, exactly  $k = 8$  values are read from **val** and **col** during each clock cycle. This is accomplished by striping these vectors across multiple memory banks. To avoid large multiplexers and the associated degradation in performance, the matrix rows are simply padded with zeros (as needed) to ensure they have an exact multiple of  $k$  values. The **ptr** vector is modified to express indices in terms of  $k$ -sized groups of data, and the term  $kn_z$  (analogous to  $n_z$ ) is the number of  $k$ -groups. This entire process, which is carried out by the software module when it marshals the data for the FPGA-based processor, is known as “ $k$ -alignment.” This  $k$ -alignment process produces scalar  $kn_z$  and vectors **kval**, **kcol**, and **kptr**. As before,  $kptr_{n+1} \equiv kn_z + 1$ .

Perhaps the idea is better understood by way of an example. If one assumes that  $k = 2$ , then the sparse matrix represented in Fig. 2.9 could be represented in  $k$ -aligned CSR format as shown in Fig. 2.10. Each bracketed  $k$ -group of data represents the contents at a

given index across a striped data set. Consider  $kptr_4 = 5$ ; this indicates that matrix row 4 begins at index 5 of striped memory banks **kval** and **kcol**. Notice  $kval_5 = [4, 7]$  (2 banks,

	1	2	3	4	5
<b>kval</b>	[8, 2]	[3, 0]	[5, 0]	[6, 1]	[4, 7]
<b>kcol</b>	[1, 3]	[4, 0]	[2, 0]	[3, 4]	[2, 4]
<b>kptr</b>	1	3	4	5	6

Figure 2.10 Example of aligned CSR format ( $k = 2, kn_z = 5$ )

2 values) and that  $kcol_5 = [2, 4]$  (2 banks, 2 indices). Thus, as in the dense matrix of Fig. 2.9,  $a_{4,2} = 4$  and  $a_{4,4} = 7$ .

## 2.5 Test Matrices

During this research it became increasingly apparent that the complexity of the matrix itself played a significant role when analyzing the number of iterations and convergence rate. Conditioning sparse matrices into a form more suitable for numerical solution, or preconditioning (Axelsson 1996), resulted in rapidly converging solutions using the software version of CG, thereby rendering the speedup which had hoped to be obtained via the fully pipelined and parallelized hardware version counterproductive. Though preconditioning is the key to a successful iterative solver such as conjugate gradient (Song ), the following section will discuss the ill-conditioned(non-preconditioned) matrices

employed that greatly challenge CG in addition to obtaining a significant speedup via a HPHC.

### 2.5.1 UFL Sparse Matrix Collection

The University of Florida Sparse Matrix Collection, managed by Dr. Tim Davis and Dr. Yifan Hu, is a large and actively growing set of sparse matrices widely used by the numerical linear algebra community for the development and performance evaluation of sparse matrix algorithms such as conjugate gradient. The collection covers a vast spectrum of domains ranging from mathematics and physics, to civil engineering and computer science. With over 2547 matrices, UFL's Sparse Matrix Collection boasts its largest matrix as having a dimension of 118 million with almost 2 billion nonzero entries (Davis and Hu 2011). UFL provides a Java program(UFgui) for browsing and downloading matrices in Matrix Market format and the complexity of the matrix itself can be manipulated by the user. Included with this software is an option for rendering images that correlate to the matrix generated by the user.

## 2.6 SRC-7

### 2.6.1 Target HPHC

The Jackson State University research group's HPHC, SRC-7, has two 3.0GHz Intel Xeon processors with a 16K L1 cache, 2MB L2 cache, and 6GB RAM. The MAP Series H processor contains two Altera EP2S180F1508C3 FPGAs running at 150MHz. It has

Figure 2.11 SRC-7 HPHC architecture

two 1GB banks of global common memory (GCM), which are used to marshal large data sets from the Xeon processor to the MAP processor and to return large data sets from the MAP to the Xeon. The Xeons access GCM via API calls, and the FPGAs access the GCM via DMA. GCM is the primary mechanism by which the GPP and FPGA interchange large data sets, i.e., GCM is used for bulk data transfers (as opposed to individual array elements). GCM can be accessed by the GPP via API calls and by the FPGA via direct memory access (DMA).

There are 16 banks of on-board memory (OBM) associated with the FPGAs. Each bank contains over 500K 64-bit words and can be separately addressed. This allows the

MAP processor to simultaneously access up to 16 words per clock cycle. OBM is the primary mechanism by which large data sets can be striped for parallel consumption by the FPGA, i.e., up to 16 values can be read from OBM each FPGA clock cycle. DMA can be used to move data between the OBM and Xeon memory, but the use of GCM is more efficient. The MAP processor is connected to the Xeon GPP motherboard through SRC's proprietary SNAP D interface, which is mapped into the Xeon memory subsystem.

The MAP processor has a streaming DMA capability and an inter/intra-FPGA streaming capability that allows computation to overlap communication and facilitates parallelism within the MAP processor. Multiple configurable single-port BRAMs are located within the FPGA fabric. The BRAMs are typically used to hold arrays that are accessed serially. A single value can be read from each BRAM array during a given clock cycle.

### 2.6.2 HLL development flow

Vendors such as Mentor Graphics and Altera have created compilers, DK Design Suite (Mentor Graphics 2010) and Carte C (SRC Computers Inc. 2014), respectively, that takes the hassle out employing HDL-based hardware design. These HLL-to-HDL compilers allow scientists and engineers to program HPHCs using HLLs like C or Fortran, which in the past, was limited to only using complex HDLs. HLL-to-HDL compilers support enhanced language features such as pipelined loops, parallel code blocks, synchronization

primitives, and intellectual property interface (IPI) calls to access vendor or user IP cores.

Figure 2.12 depicts an HLL development flow for HPHC-based applications.

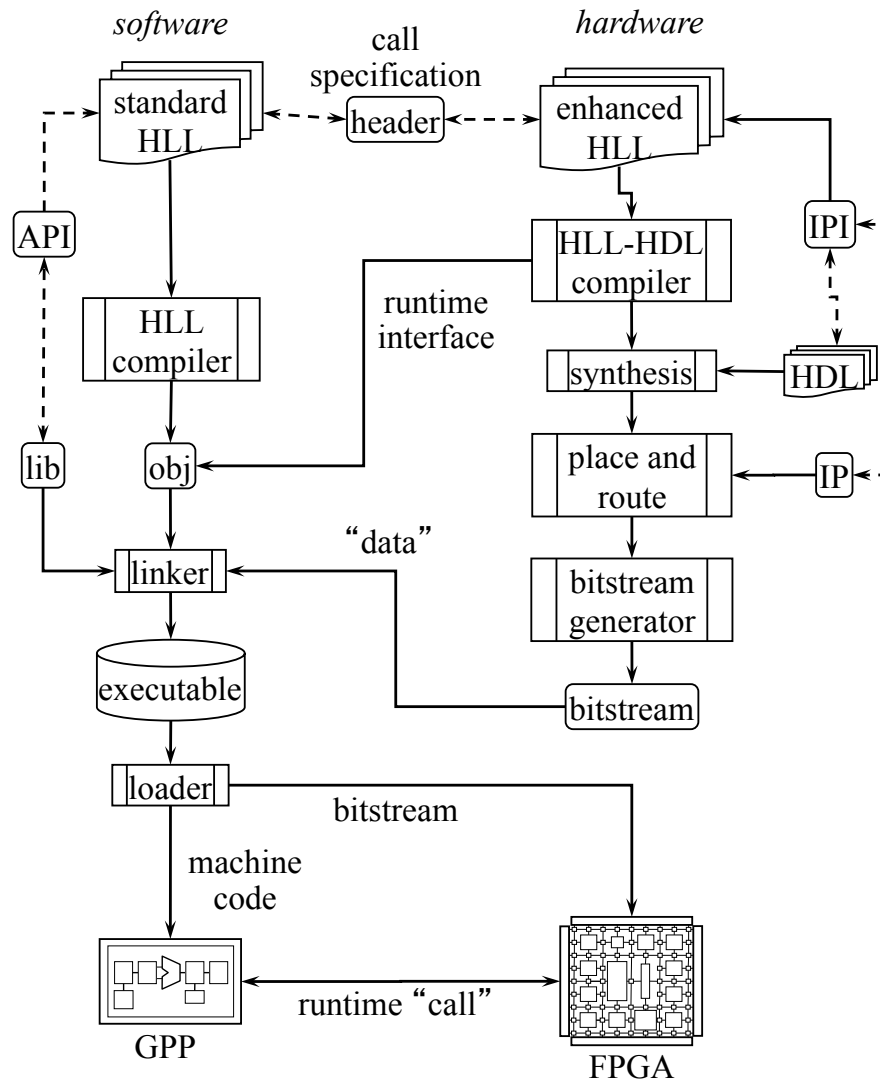

Figure 2.12 HLL development flow

The application is partitioned into software modules, which are targeted for execution on the GPP(s), and hardware modules, which are targeted for execution on the FPGA(s). Developers can also integrate custom HDL-based IP cores into their design. During development, the HLL software module is compiled with a standard HLL compiler to produce object files. The linker uses the object files (including the hardware module runtime interface code emitted by the HLL-to-HDL compiler), library files, and the configuration bitstream (treated as data by the linker) to produce a binary executable. The enhanced HLL hardware module is ingested by the HLL-to-HDL compiler, which emits HDL and the runtime interface code previously mentioned. The HDL is used by the synthesis tool to produce a netlist. The netlist, which topologically details the low-level device instances and connections needed to implement the logic circuit, is fed into the place and route tool. As suggested by the name, the place and route tool determines an optimal way to implement an instance of the netlist subject to a set of constraints, e.g., area, timing.

The output of place and route is fed to the bitstream generation tool to produce an FPGA configuration bitstream. The bitstream, when loaded onto the FPGA, configures the programmable logic, interconnection network, and I/O of the FPGA such that it implements the logic design representing the computational kernel. From the viewpoint of the software module, as suggested by the header file block at the top of figure 2.12, the hardware module “looks like” a parameterized subroutine call. From the viewpoint of the hardware module HLL code, IP cores also look like subroutine calls via the IPI. At

execution time, the configuration bitstream is extracted from the binary executable and loaded onto the FPGA. The GPP then executes the machine code instructions and “calls” the FPGA-based kernel as needed.

## 2.7 Amdahl’s Law

Gene Amdahl, a Norwegian American computer architect who has worked extensively on mainframe computing at IBM and later his own companies, is best known for formulating Amdahl’s law, which states a fundamental limitation of parallel computing (IEEE 2014). Amdahl’s law or Amdahl’s argument, is used to find the maximum expected improvement to an overall system when only part of the system is improved. It is often used in parallel computing to predict the theoretical maximum speedup using multiple processors, however, Amdahl’s law also encompasses the domain of RC systems as well (Amdahl 1967).

Amdahl’s law is a model for the relationship between the expected speedup of parallelized implementations of an algorithm relative to the serial algorithm, under the assumption that the problem size remains the same when parallelized. Equation 2.3 gives the formula for Amdahl’s law.

$$s_o = \frac{1}{1 - f_e + f_e/s_e}, \quad (2.3)$$

where  $s_o$  is the overall speedup,  $f_e$  is the fraction of the system to be enhanced, and  $s_e$  is the speedup of the portion to be enhanced. For example, if 75 percent, i.e., the fraction to be enhanced, of an algorithm can be parallelized, and 25 percent is sequential, according

to Amdahl's law, the overall speedup which can be achieved on three processors, i.e., the portion to be enhanced, is  $1/((1-.75) + (.75/3)) = 2$ . This means that the overall speedup,  $s_o$ , the program can gain is twice as fast on three processors than on one. Amdahl's law is used within this research to statically analyze the overall speedup of the monolithic and tuned versions of CG. The details are discussed in Chapter 3.

## CHAPTER 3

### METHODOLOGY

#### 3.1 Overview

High performance heterogeneous computers that employ field programmable gate arrays (FPGAs) as computational elements are known as high performance heterogeneous computers (HPHCs). For floating-point applications, these FPGA-based processors must satisfy a variety of heuristics and rules of thumb to achieve a speedup compared with their software counterparts. By way of a sparse matrix conjugate gradient iterative solver, the following sections illustrates the methods associated with mapping floating-point kernels onto HPHCs.

It is worthwhile looking at some of the rules of thumb and heuristics used to determine if CG is a good mapping candidate. These have been developed over the past several years based on Jackson State University's HPHC-oriented research and are described in some detail in (Rice, Pace, Gates, Morris, and Abed 2008; Justin L. Rice and Morris 2009). Considerations include: (a) the three p's, (b) expected resource utilization, (c) control/memory vs. compute intensive, (d) monolithicity, (e) available bandwidth, (f) opportunities for data reuse, (g) algorithm design stability, (h) algorithm efficiency, and (i) memory access patterns. Section 3.2 gives more details about these design considerations relative to CG.

There are currently two pairs (monolithic and “tuned”) of the floating-point sparse matrix CG iterative solver in reference with this research. The two monolithic versions blindly mapped the *entire* CG algorithm. The first version executes strictly on software, i.e., the GPP. The second utilizes both the GPP and the SRC-7 HPHC. Section 3.4 details the monolithic versions while also giving an overview of the pitfalls associated with CG when the rules and heuristics of mapping floating-point kernels onto HPHCs are not considered. The “tuned” pair are refactored versions of CG. CG was statically analyzed to determine where the most computational expensive operations occur, which is MVM. Through the use of a system call, CG was redeveloped to initiate MVM as a separate subroutine. Section 3.5 discusses both the software and hardware versions of the profiled CG algorithm, a detailed discussion of MVM, and the analytics used for the theoretical overall speedup via Amdahl’s Law.

### 3.2 The JSU-team rules and heuristics

#### 3.2.1 The three p’s

The three p’s, which expresses the crucial relationship among performance, pipelining, and parallelism, is perhaps the most important mapping consideration (Morris and Abed 2013). The multiplicative effect of both pipelining and parallelizing is suggested by Eq. 3.1:

$$performance \propto pipelined \times parallelized \quad (3.1)$$

Given the order-of-magnitude clock speed advantage of GPPs over FPGAs, a candidate FPGA module must be able to be both pipelined and parallelized if a performance improvement is to be realized.

### 3.2.2 Expected resource utilization

Another important consideration is the expected FPGA resource utilization of the candidate module. Since floating-point IP cores can be quite large, the developer needs to determine if the candidate will even fit on the FPGA. The developer also needs to consider the needed local memory capacity, number of simultaneous memory accesses, anticipated clock rate in the light of complex routing, etc. In the case of the CG solver, the limiting factor was the amount of BRAM in the FPGA fabric, with the number of OBM banks running a close second. Despite these limitation an 8-wide parallel CG data path capable of handling sparse matrices up to order,  $n = 8K$ , with up to approximately 4M nonzero entries was constructed.

### 3.2.3 Control/memory vs. compute intensive

It is also imperative to consider whether an algorithm is control/memory intensive or compute intensive. The control aspect is similar to the branching problem in a GPP, and the memory aspect is similar to a GPP where accessing memory data takes a considerable amount of time compared with arithmetic operations. Harkins, et al., (Harkins, El-Ghazawi, El-Araby, and Huang 2005) illustrate the importance of this concept when they show that sorting algorithms do not perform very well on an HPHC.

The CG processor employs design features that minimize the number of control clauses, e.g., the use of  $k$ -aligned CSR format. Furthermore, unlike a GPP memory hierarchy, the HPHC memory organization does not penalize irregular memory accesses (Abed and Morris 2009). Therefore, on an FPGA, CG appears to be primarily compute intensive.

### 3.2.4 Monolithicity

If the candidate FPGA module contains procedure calls (is not monolithic), then these calls have to be inlined or the module cannot be considered as a viable candidate (hardware cannot “call” hardware). Obviously, the ability to inline is impacted by the available FPGA resources. In the case of the CG processor, the Carte compiler provided IPI “calls” for some of the lower level “routines” such as square root. Therefore, the first CG kernel pair was effectively monolithic and suitable for mapping onto an FPGA. In addition, a second refactored pair of CG kernels had a software subroutine that called MVM which is also monolithic.

### 3.2.5 Available bandwidth

The GPP to FPGA bandwidth also deserves attention. Obviously, the FPGA memory access and processing time should be less than the GPP memory access and processing time. According to Herbordt, et al., (Herbordt, Court, Gu, Sukhwani, Conti, Model, and DiSabello 2007), when they discuss latency hiding, a design should try to overlap computation with communication. In the CG processor a reduction in the bandwidth

requirement was achieved by marshaling the data into GCM banks and then using DMA to load the OBM and BRAM memory used during the FPGA-based computation.

### 3.2.6 Opportunities for data reuse

Algorithms that have a significant potential for data reuse may be suitable FPGA module candidates. In the case of the CG iterative solver, the matrix  $A$  and vector  $b$  are reused during every iteration. This had the effect of amortizing the transfer costs across all iterations.

### 3.2.7 Algorithm design stability

Since mapping an algorithm to an FPGA is not the easiest of tasks, it is imperative to make sure that the algorithm is as stable as possible. If the algorithm is altered while in the midst of a hardware implementation process, one could easily discover that the new algorithm no longer fits onto the FPGA, or that it can no longer deliver on the promised speedup. The CG iterative solver has been around for over six decades; obviously the authors did not anticipate any algorithm design modifications.

### 3.2.8 Algorithm efficiency

Another application design consideration is to make sure an efficient algorithm is employed. For example, Cramer's rule, which has exponential complexity,  $O((n + 1)!)$ , might run faster if implemented on an FPGA. However, Gaussian elimination, with complexity,  $O(n^3)$ , is a much more efficient algorithm. In this case, one would use a

software solution rather than map the inefficient algorithm onto an FPGA. In the case of the CG algorithm, Section 2.3 identifies CG as being one of the most efficient algorithms for solving large sparse systems of linear equations.

### 3.2.9 Memory access patterns

Another design consideration is the memory access pattern. Unlike a GPP memory hierarchy, the HPHC memory organization does not penalize irregular memory accesses (Abed and Morris 2009). Since the CG processor uses a sparse matrix, it clearly demonstrates an irregular memory access pattern and is a good mapping candidate.

## 3.3 High-level design

### 3.3.1 CG

The high-level design for the CG solver is shown in Fig. 3.1. It consists of four major components: a main routine and matrix support libraries; several strictly diagonally dominant sparse matrices,  $A_1 \dots A_m$ ; the software or hardware (FPGA-based) CG solver; and the output result and statistics files,  $\mathbf{x}_1 \dots \mathbf{x}_m$  and  $\Theta_1 \dots \Theta_m$ . The  $\mathbf{b}_i$  vectors are shown as inputs, but for the experiments in this research they are generated from a known  $\mathbf{x}$  vector at runtime. The main routine is a driver program, which essentially measures how long it takes for CG to solve each set of equations. The coordinate-format matrices are read in using the Matrix Market I/O library (NIST 2004) and converted to CSR format using Saad's SPARSKIT library (Saad 2009). The software CG kernel implementation

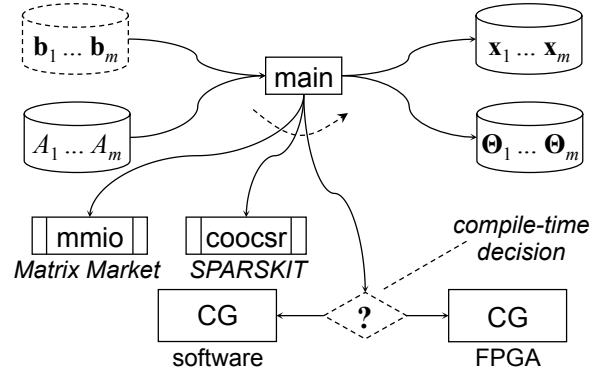

Figure 3.1 High-level CG design

is based on the algorithm shown in Figure 2.6, and the FPGA-based CG kernel will be described in Section 3.4.

A compile-time decision selects either the software or FPGA-based version of CG. At runtime, main reads in each coordinate-format matrix, converts it to CSR format, and uses a known  $x$  vector to generate  $b$ . It then invokes the selected CG kernel sending matrix,  $A$  ( $val$ ,  $col$ , and  $ptr$ ), starting point  $x^{(0)}$ , and constant vector  $b$ . After convergence, CG stores the result and returns. The main routine writes the solution to the results file; it also writes the input matrix name, number of iterations, and wall clock execution time to the statistics file and then terminates.

### 3.3.2 MVM

To recap, there were four CG algorithms that were mapped onto the HPHC. The first pair was a monolithic version which comprised of a software and hardware version. The second pair was "tuned" and also had a software and hardware version, however, this

kernel involved a subroutine call that implemented MVM; software or hardware. In other words, the high-level design for the "tuned" CG solver is very similar to Figure 3.1, however, in this kernel CG invokes MVM to either compute the software or hardware version as illustrated in Figure 3.2.

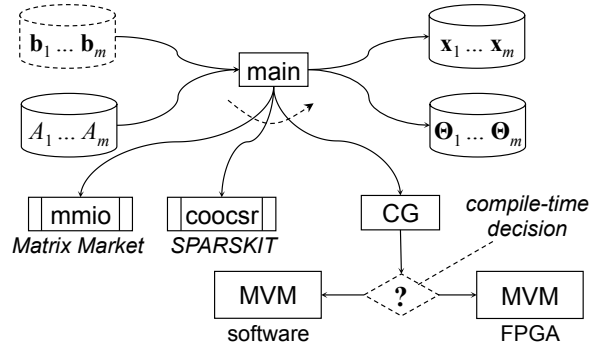

Figure 3.2 High-level MVM design

### 3.4 Monolithic version

#### 3.4.1 Software

As stated in Section 1, our research began by blindly mapping the entire CG algorithm onto hardware without any regard to the heuristics that previous research has shown to highly impact performance. The monolithic CG algorithm that was executed in software, i.e., the GPP, is essentially the algorithm depicted in Figure 2.6.

### 3.4.2 Hardware

The monolithic hardware version of CG is shown in Figure 3.3.

```

1: algorithm CGHW(kval, kcol, kptr, b, b2, n, knz, x)
2:   parBegin // only two GCM banks so
3:     BUF_DMAGCM1:OBM (kval, stripe-8)
4:     BUF_DMAGCM2:OBM (kcol, stripe-8)
5:   parEnd
6:   parBegin // parallel DMA limited to 2
7:     STREAM_DMAGCM1:BRAM (kptr)
8:     STREAM_DMAGCM2:BRAM (b)
9:   parEnd
10:  for  $i$  in  $[1, n]$  do // set up for repeat loop
11:     $x_i \leftarrow 0$  //  $x = 0$

49:     $r2b2 \leftarrow \sqrt{(rTold)b2}$  // residual norm
50:     $d \leftarrow d + 1$  // next iteration
51:  until ( $r2b2 \leq \epsilon$ ).OR. ( $d > d_{\max}$ )
52:  STREAM_DMABRAM:GCM2 (x) // all done, stream x back to GCM
53: end algorithm

```

Figure 3.3 monolithic hardware version of CG

The loops on line 35 and 42 are serialized loops, therefore, they cannot be done in parallel with the dot product, i.e., line 37. Consequently, these serial loops will incur costly computational penalties that significantly decreases the speedup. A block diagram is also presented here to further illustrate the algorithm.

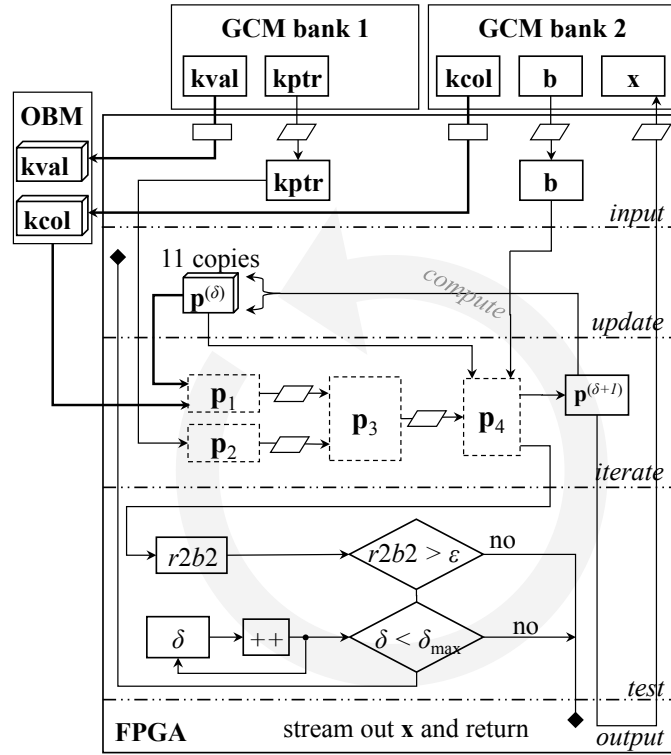

Figure 3.4 CG hardware process

### 3.5 “Tuned” version

#### 3.5.1 Software

This algorithm is essentially the same as the discussion held in the previous section, however, this software features a subroutine call to MVM as shown in Figure 3.5. A static

```

1: algorithm CGSW( $A, \mathbf{x}, \mathbf{b}$ )
2:    $\mathbf{p}_1 \leftarrow \mathbf{b} - A\mathbf{x}_0$ 
3:    $\mathbf{r}_0 \leftarrow \mathbf{p}_1$ 
4:    $\Delta \leftarrow \epsilon + 1$ 
5:    $\text{over}b_{\text{norm}} \leftarrow 1/\|\mathbf{b}\|$ 
6:    $rTr_{\text{old}} \leftarrow \mathbf{r}_0^T \mathbf{r}_0$ 
7:    $k \leftarrow 1$ 
8:   while ( $\Delta > \epsilon$ ) .AND. ( $k < k_{\text{max}}$ ) do
9:      $\mathbf{v}_{ap} \leftarrow \text{mvm}(\mathbf{a}, \mathbf{p})$ 
10:     $\alpha_k \leftarrow rTr_{\text{old}}/\mathbf{p}_k^T \mathbf{v}_{ap}$ 
11:     $\mathbf{x}_k \leftarrow \mathbf{x}_{k-1} + \alpha_k \mathbf{p}_k$ 
12:     $\mathbf{r}_k \leftarrow \mathbf{r}_{k-1} - \alpha_k \mathbf{v}_{ap}$ 
13:     $rTr_{\text{new}} \leftarrow \mathbf{r}_k^T \mathbf{r}_k$ 
14:     $\beta_k \leftarrow rTr_{\text{new}}/rTr_{\text{old}}$ 
15:     $rTr_{\text{old}} \leftarrow rTr_{\text{new}}$ 
16:     $\mathbf{p}_{k+1} \leftarrow \mathbf{r}_k + \beta_k \mathbf{p}_k$ 
17:     $\Delta \leftarrow \|\mathbf{r}_k\| \cdot \text{over}b_{\text{norm}}$ 
18:     $k++$ 
19:   end while
20:   return ( $\mathbf{x}_{k-1}$ )
21: end algorithm

```

Figure 3.5 tuned software version of CG

analysis of CG showed that the matrix-vector multiply, which is  $O(n^2)$ , was the most expensive part of the kernel. Therefore, CG was refactored such that matrix-vector

multiply was a separate routine. Subsequently, `gprof` was used to profile the software version of the code. Not surprisingly, matrix vector multiply consumed nearly 67 percent of the runtime, therefore, according to Amdahl's law, the fraction to be enhanced  $f_e = 0.67$ .

### 3.5.2 Hardware

The tuned hardware CG algorithm is exactly as previously discussed , except a call to MVM is a call to hardware, as shown in Figure 3.6. The objective of mapping algorithms onto HPHCs is to obtain a speedup relative to the performance on a GPP. Anticipated overall speedup can be quantified via Amdahl's Law (J. L. Hennessy and D. A. Patterson 2003)

$$s_o = \frac{1}{1 - f_e + f_e/s_e},$$

where  $s_o$  is the overall speedup,  $f_e$  is the fraction of the system to be enhanced, and  $s_e$  is the speedup of the portion to be enhanced.

The SRC-7 MAPstation used as the target platform has two Intel Xeon processors and two Altera FPGAs running at 3.0GHz and 150MHz, respectively. In the absence of parallelization or pipelining, the FPGA runs 20x slower than the GPP, i.e.:

$$s_e = \frac{150Mhz}{3000Mhz} = \frac{1}{20}$$

```

1: algorithm MVMHW(kval, kcol, kptr, v, p, *first)
2:   if (*first) then                                     // grab the A matrix
3:     parBegin                                             // only two GCM banks so
4:       BUF_DMAGCM1:OBM (kval, stripe-8)
5:       BUF_DMAGCM2:OBM (kcol, stripe-8)
6:     parEnd
7:     parBegin                                             // parallel DMA limited to 2
8:       STREAM_DMAGCM1:BRAM (kptr)
9:       STREAM_DMAGCM2:BRAM (p)
10:    parEnd
11:  else                                                    // matrix A is already in memory
12:    STREAM_DMAGCM2:BRAM (p)                               // still need p
13:  end if
14:  p1 ← ... ← p8 ← p
15:  parBegin                                               // compute v = Ap
16:    p1:                                                    // feed values stream
17:    for i in [1, knz] do
18:      a ← (a1 ... a8) stripe-8 from kvali
19:      j ← (j1 ... j8) stripe-8 from kcoli
20:      p ← (p1j1 ... p8j8)
21:      VFIFO ← dot8Tree (a, p)
22:    end for
23:    p2:                                                    // feed counts stream
24:    for i in [1, n] do
25:      CFIFO ← kptri+1 - kptri
26:    end for
27:    p3:                                                    // streaming accumulator
28:    SFIFO ← ΣSTREAM(VFIFO, CFIFO)
29:    p4:                                                    // the dotN's
30:    for i in [1, n] do
31:      vi ← SFIFO
32:    end for
33:  parEnd
34:  STREAM_DMABRAM:GCM2 (v)                               // all done, return results
35: end algorithm

```

Figure 3.6 tuned hardware version of CG

The width of the dot product tree is 8 and the depth of the pipeline is approximately 50 (recall that the speed-up of a pipeline for a large number of items is the same as the depth). Thus, parallization and pipeling results in

$$s_e = \frac{8 \times 50}{20} = 20.$$

There are some serial operations and latencies that cannot be hidden during computation, so a conservative value is  $s_e \approx 10$ . Therefore, according to Amdahl's Law, an overall speedup  $s_o = 1/(0.33 + 0.67/10) = 2.5$  is anticipated.

## CHAPTER 4

### RESULTS, ANALYSIS, AND COMPARISON

#### 4.1 Results

##### 4.1.1 Monolithic results

As shown in table 4.1, a monolithic approach might not produce a speedup. In our example, it produced a slowdown as depicted by the average of six samples of matrices. This is to be expected since the monolithic version of CG disregarded the rules and heuristics when mapping algorithms onto HPHCs.

Table 4.1 Slowdown using monolithic method

Matrix Name	Size (NZ)	$t_{sw} (\mu s)$	$t_{hw} (\mu s)$	Slowdown $\left(\frac{t_{hw}}{t_{sw}}\right)$
fass1.128.mtx	438	66381	258797	3.89
fass2.500.mtx	2298	55247	435985	7.89
fass1.1024.mtx	4918	396983	286116	0.72
fass1.2048.mtx	10038	74304	300623	4
fass4.4096.mtx	26270	398214	3759980	9.4
fass1.8192.mtx	40758	150452	490218	3.25
			Avg. slowdown	4.85

#### 4.1.2 Tuned results

In contrast, following the heuristics, discussed in Section 3.2, it is possible to achieve a speedup. Due to technical difficulties, our target platform is undergoing repairs at the vendor's site, therefore, it is not possible to show the results of the refactored CG hardware mapping. Nonetheless, previous research mapping scientific kernels such as Transactions on Parallel and Distributed Systems' (TPDS) paper "Mapping a Jacobi Iterative Solver onto a High Performance Heterogeneous Computer" resulted in a 3-fold increase in performance as illustrated in Fig 4.1.

Figure 4.1 Run time comparison

The refactored CG algorithm that calls the hardware MVM is in close agreement with these speedups based upon the static analysis in Section 3.5.

## CHAPTER 5

### CONCLUSIONS AND FUTURE WORK

The research thus far has suggested strong evidence of an overall speed up of conjugate gradient (CG) when the rules and heuristics developed by the Jackson State University's High Performance Heterogeneous Computers (HPHC) research group are adhered to. The negative impact of performance has also been illustrated when these rules and heuristics are ignored (Hawkins, Alfarrar, Morris, and Abed ). Finding the "sweet spot" when mapping scientific kernels onto HPHCs has indeed helped in solidifying the veracity of the University's extensive research within the HPHC research domain (Rice, Abed, and Morris 2009; Rice, Pace, Gates, Morris, and Abed 2008; Justin L. Rice and Morris 2009; Morris, Silas, and Abed 2012; Morris 2006). Due to our target platform being upgraded from ARO funds at this current time, further progress in the research had to be postponed until the HPHC returns from the vendor. Future work includes finishing the hardware implementation of matrix vector multiplication (MVM) and calculating the actual overall speedup of CG.

## A.2 "Tuned" Conjugate Gradient Development

### A.2.1 main2.c

```

1286 /* main.c
1287     sparse matrix jacobi iterative solver for SRC-7 hardware
1288     Gerald R. Morris , gerald.r.morris@us.army.mil , 1 Mar 10
1289     refactored by Gerald R. Morris , 7 Apr 2011 to use a
1290     residual norm-based convergence test
1291     Refactored by Jamory D. Hawkins and Anas Alfarra ,Dec 2013
1292     to use conjugate gradient as the iteration method

```

```

1293
1294   There are actually two options when building this code
1295   The options are selected via defines in the mvm.h header file
1296   #define SWVER    or    #define HWVER
1297   The first is the software version which employs the standard
1298   nested loop approach to do the calculation serially.
1299   The second is the k-aligned hardware version, which employ loops
1300   wherein the matrix is dealt with in chunks of k elements at a time.
1301   k-alignment requires an exact multiple of k elements in a row
1302   The k-alignment process simply pads the matrix with 0's
1303   */
1304   #include <stdio.h>

## A.3 Performance Evaluation Application

### A.3.1 usec.h

```

2348 // usec.h
2349 // need usec time resolution to measure performance
2350 double usec(void);

```

### A.3.2 usec.c

```

2351 #include <sys/time.h>
2352 #include <stdlib.h>
2353 //-----
2354 // need microsecond resolution to measure performance
2355 double usec(void) {
2356
2357     struct timeval t0; // time
2358
2359     gettimeofday(&t0,NULL);
2360
2361     // if we overrun the epoch, boom!

```

```
2362     // we'll assume this seldom happens!!  
2363     return ((double)(t0.tv_sec*1e6+t0.tv_usec));  
2364 }
```

## VITA

Jamory Dante Hawkins [REDACTED]. He attended Lanier High School and immediately following graduation, enrolled in Hinds Community college in 2006. On December 12, 2008, Mr. Hawkins received his Associate of Arts degree from Hinds and the following month, in January 2009, enrolled in Jackson State University's Computer Engineering program.

Mr. Hawkins received his Bachelor of Science degree in Computer Engineering on December 8, 2012, continued with his academic goals, and is pursuing a MS degree in Computer Engineering in addition to joining Jackson State University's HPRC research group. During his years of study, he was employed as a graduate research assistant. He has also interned at the U.S. Army Corps of Engineers, Engineer Research and Development Center in Vicksburg, Mississippi. On December 19, 2013, Mr. Hawkins accepted a federal civilian position within the U.S. Department of the Navy's Naval Surface Warfare Center (NSWC) as a Computer Engineer. He is expected to begin his career at the NSWC and receive his Master of Science degree in Computer Engineering in May 2014.
